ABSTRACT

We examine the properties of the host galaxies of 22 623 narrow-line active galactic nuclei (AGN) with $0.02 < z < 0.3$ selected from a complete sample of 122 808 galaxies from the Sloan Digital Sky Survey. We focus on the luminosity of the [O III] $\lambda 5007$ emission line as a tracer of the strength of activity in the nucleus. We study how AGN host properties compare with those of normal galaxies and how they depend on $L[\text{O III}]$. We find that AGN of all luminosities reside almost exclusively in massive galaxies and have distributions of sizes, stellar surface mass densities and concentrations that are similar to those of ordinary early-type galaxies in our sample. The host galaxies of low-luminosity AGN have stellar populations similar to normal early types. The hosts of high-luminosity AGN have much younger mean stellar ages. The young stars are not preferentially located near the nucleus of the galaxy, but are spread out over scales of at least several kiloparsecs. A significant fraction of high-luminosity AGN have strong H δ absorption-line equivalent widths, indicating that they experienced a burst of star formation in the recent past. We have also examined the stellar populations of the host galaxies of a sample of broad-line AGN. We conclude that there is no significant difference in stellar content between type 2 Seyfert hosts and quasars (QSOs) with the same [O III] luminosity and redshift. This establishes that a young stellar population is a general property of AGN with high [O III] luminosities.

Key words: galaxies: active – galaxies: Seyfert – galaxies: starburst – galaxies: stellar content – galaxies: structure.

1 INTRODUCTION

The discovery of a tight correlation between black hole mass and bulge velocity dispersion (Ferrarese & Merritt 2000; Gebhardt et al. 2000) gives credence to theoretical arguments that spheroid formation and the growth of supermassive black holes are closely linked (e.g. Richstone et al. 1998; Haehnelt, Natarajan & Rees 1998; Kauffmann & Haehnelt 2000; Monaco, Salucci & Danese 2000). Active galactic nuclei (AGN) are believed to be powered by the accretion of gas on to black holes located at the centres of galaxies (Lynden-Bell 1969). AGN thus signpost galaxies in which black holes are forming, and it is natural to hypothesize that at least some

AGN should be found in young spheroids. Direct observational evidence in support of this hypothesis remains controversial, however.

Recent *Hubble Space Telescope* (HST) imaging studies of quasar (QSO) host galaxies at low redshifts have found that the majority of the most luminous QSOs reside in early-type galaxies [e.g. Bahcall et al. (1997) and McLure et al. (1999) find that around 15 per cent of the QSOs in their sample are found in spirals]. Although a subset of QSO host galaxies exhibit disturbed morphologies (Percival et al. 2001), the stellar populations of these hosts appear indistinguishable from those of normal elliptical galaxies (McLure, Dunlop & Kukula 2000).

The claim that luminous QSOs are located in old ellipticals sits uncomfortably with the results of several major spectroscopic investigations that have confirmed the presence of young stars in

*E-mail: gamk@mpa-garching.mpg.de

at least half of all powerful narrow-line or type 2 Seyfert nuclei (Schmitt, Storchi-Bergmann & Cid Fernandes 1999; González Delgado, Heckman & Leitherer 2001; Cid Fernandes et al. 2001; Joguet et al. 2001). There is also considerable evidence that the properties of AGN hosts depend strongly on the luminosity of the central source. The lowest-luminosity AGN, the low-ionization nuclear emission regions (LINERs), have [O III] $\lambda 5007$ and H α narrow-line region (NLR) emission-line luminosities in the range $\sim 10^5$ – $10^6 L_\odot$. LINERs are found in galaxies of earlier Hubble type than Seyfert galaxies, and their nuclear continua are usually dominated by old stars (Heckman 1980a,b; Ho, Filippenko & Sargent 2003).

Up to now, studies of AGN host galaxies have been limited by small sample size. In order to carry out detailed statistical analyses of host galaxy properties, one requires complete magnitude-limited samples of galaxies with spectra of high enough quality to identify AGN based on the characteristics of their emission lines. A catalogue of 26 type 1 Seyfert galaxies, 23 type 2 Seyfert galaxies and 33 LINERs identified in the CfA Redshift Survey (Huchra & Burg 1992) has formed the basis of many follow-up studies. De Grijs et al. (1992) identified ~ 220 Seyfert galaxies from a sample of 563 *IRAS* sources selected from the Point Source Catalog. Most recently, Ho, Filippenko & Sargent (1995) carried out a survey of 486 nearby bright galaxies from the Revised Shapley–Ames Catalog with $B < 12.5$. The proximity of the galaxies in this survey meant that very high spatial resolution of the nuclear regions of the galaxies could be achieved. In addition, the spectra were of high quality, enabling the detection of relatively weak emission lines. Ho et al. found that 43 per cent of the objects in their sample could be classified as AGN, a significantly higher fraction than in previous surveys of galaxies selected at optical wavelengths.

This paper examines the properties of 22 623 narrow-line AGN selected from a complete sample of 122 808 galaxies from the Sloan Digital Sky Survey with r -band magnitudes in the range $14.5 < r < 17.7$. The relations between stellar mass, star formation history, size and internal structure for the galaxies in the parent sample are described in a recent paper by Kauffmann et al. (2003b, hereafter Paper II), where it was found that ordinary galaxies divide into two distinct families at a stellar mass of $3 \times 10^{10} M_\odot$. Low-mass galaxies have young stellar populations, low surface mass densities and the low concentrations typical of discs. At stellar masses above $3 \times 10^{10} M_\odot$, a rapidly increasing fraction of galaxies has old stellar populations, high surface mass densities and the high concentrations typical of bulges. The star formation histories of galaxies correlate most strongly with surface mass density, with a transition from ‘young’ to ‘old’ stellar populations occurring at $\mu_* \sim 3 \times 10^8 M_\odot \text{ kpc}^{-2}$.

In this paper, we compare the properties of AGN hosts with those of normal galaxies. The properties that we study include stellar masses, sizes and surface densities, as well as stellar ages and past star formation histories, as deduced from key spectral features such as 4000-Å break strengths and the equivalent widths of Balmer absorption lines. We also study how these properties vary as a function of AGN luminosity as measured by the strength of the [O III] $\lambda 5007$ emission line. Section 2 reviews the properties of the galaxy sample and the methods used to derive parameters such as stellar mass, dust attenuation strength and burst mass fraction. In Section 3, we describe how type 2 AGN are identified and classified and we investigate whether a ‘featureless’ non-stellar continuum can affect our conclusions about stellar ages and star formation histories. In Section 4, we present a step-by-step comparison of the properties of type 2 AGN hosts with those of normal galaxies. Section 5 compares the stellar populations of the most powerful type 2 AGN in

our sample with those of type 1 AGN of the same [O III] luminosity and redshift. Finally, in Section 6, we show images of representative examples of our most powerful AGN and discuss the implications of our results.

Throughout this paper we assume a Friedman–Robertson–Walker cosmology with $\Omega = 0.3$, $\Lambda = 0.7$ and $H_0 = 70 \text{ km s}^{-1} \text{ Mpc}^{-1}$.

2 REVIEW OF THE SPECTROSCOPIC SAMPLE OF GALAXIES

The Sloan Digital Sky Survey (SDSS; York et al. 2000; Stoughton et al. 2002) is using a dedicated 2.5-m wide-field telescope at the Apache Point Observatory to conduct an imaging and spectroscopic survey of about a quarter of the extragalactic sky. The imaging is conducted in the u , g , r , i and z bands (Fukugita et al. 1996; Gunn et al. 1998; Hogg et al. 2001; Smith et al. 2002), and spectra are obtained with a pair of multifibre spectrographs. When the current survey is complete, spectra will have been obtained for nearly 600 000 galaxies and 100 000 QSOs selected uniformly from the imaging data. Details on the spectroscopic target selection for the ‘main’ galaxy sample and QSO sample can be found in Strauss et al. (2002) and Richards et al. (2002) respectively. Details about the tiling algorithm and the astrometry can be found in Blanton et al. (2003) and Pier et al. (2003), respectively. The results in this paper are based on spectra of ~ 122 000 galaxies with $14.5 < r < 17.77$ contained in the SDSS Data Release One (DR1). These data have been made publicly available.

The spectra are obtained through 3-arcsec diameter fibres. At the median redshift of the main galaxy sample ($z \sim 0.1$), the projected aperture diameter is 5.5 kpc and typically contains 20 to 40 per cent of the total galaxy light. The SDSS spectra are thus closer to global than to nuclear spectra. At the median redshift the spectra cover the rest-frame wavelength range from ~ 3500 to 8500 Å with a spectral resolution $R \sim 2000$ ($\sigma_{\text{instr}} \sim 65 \text{ km s}^{-1}$). They are spectrophotometrically calibrated through observations of F stars in each 3-degree field. By design, the spectra are well suited to the determination of the principal properties of the stars and ionized gas in galaxies. The absorption-line indicators (primarily the 4000-Å break strength and the $H\delta_A$ index) and the emission-line fluxes analysed in this paper are calculated using a special-purpose code described in detail in Tremonti et al. (in preparation). A detailed description of the galaxy sample and the methodology used to derive parameters such as stellar mass and dust attenuation strength can be found in Kauffmann et al. (2003a, hereafter Paper I).

The rich stellar absorption-line spectrum of a typical SDSS galaxy provides unique information about its stellar content and dynamics. However, it makes the measurement of weak nebular emission lines quite difficult. To deal with this, we have performed a careful subtraction of the stellar absorption-line spectrum before measuring the nebular emission lines. This is accomplished by fitting the emission-line-free regions of the spectrum with a model galaxy spectrum computed using the new population synthesis code of Bruzual & Charlot (2003, hereafter BC03), which incorporates a high-resolution (3 Å full width at half-maximum, FWHM) stellar library. A set of 39 model template spectra were used spanning a wide range in age and metallicity. After convolving the template spectra to the measured stellar velocity dispersion of an individual SDSS galaxy, the best fit to the galaxy spectrum is constructed from a non-negative linear combination of the template spectra.

We have used the amplitude of the 4000-Å break (the narrow version of the index defined in Balogh et al. 1999) and the strength of the $H\delta$ absorption line (the Lick $H\delta_A$ index of Worthey & Ottaviani

1997) as diagnostics of the stellar populations of the host galaxies. Both indices are corrected for the observed contributions of the emission lines in their bandpasses. Using a library of 32 000 model star formation histories, we have used the measured $D_n(4000)$ and $H\delta_A$ indices to obtain a maximum-likelihood estimate of the z -band mass-to-light ratio (M/L) for each galaxy. By comparing the colour predicted by the best-fitting model to the observed colour of the galaxy, we also estimate the attenuation of the starlight due to dust.

The SDSS imaging data provide the basic structural parameters that are used in this analysis. We use the z band as our fiducial filter because it is the least sensitive to the effects of dust attenuation. The z -band absolute magnitude, combined with our estimated values of M/L and dust attenuation A_z yield the stellar mass (M_*). The half-light radius in the z band and the stellar mass yield the effective stellar surface mass density ($\mu_* = M_*/2\pi r_{50,z}^2$). As a proxy for Hubble type we use the SDSS ‘concentration’ parameter C , which is defined as the ratio of the radii enclosing 90 and 50 per cent of the galaxy light in the r band (see Stoughton et al. 2002). Strateva et al. (2001) find that galaxies with $C > 2.6$ are mostly early-type galaxies, whereas spirals and irregulars have $2.0 < C < 2.6$.

3 IDENTIFICATION AND CLASSIFICATION OF AGN

According to the standard ‘unified’ model (e.g. Antonucci 1993), AGN can be broadly classified into two categories depending on whether the central black hole and its associated continuum and broad emission-line region are viewed directly (a ‘type 1’ AGN) or are obscured by a dusty circumnuclear medium (a ‘type 2’ AGN).

Since this obscuring medium does not fully cover the central source, some of the radiation escapes and photoionizes the surrounding gas, leading to strong narrow permitted and forbidden emission lines from the ‘narrow-line region’ (NLR). In type 1 AGN the optical continuum is dominated by non-thermal emission, making it a challenge to study the host galaxy and its stellar population. This is especially true of QSOs, where the continuum radiation from the central source outshines the stellar light from the host galaxy.

We have therefore excluded the type 1 AGN from our initial sample (but will undertake a limited analysis of such objects in Section 5). The rejection of type 1 AGN from our sample is accomplished automatically by the SDSS spectral classification algorithm, which is based on a principal component analysis (PCA) approach (Schlegel et al., in preparation). We have verified the reliability of this procedure through the manual inspection of ~ 1000 spectra of the most powerful AGN in our sample. In about 8 per cent of the cases, weak broad wings are present on the $H\alpha$ emission line, but not on $H\beta$. In the standard nomenclature (Osterbrock 1989), these would be classified as ‘type 1.9’ AGN (objects in which the obscuration of the central continuum source is substantial, but not complete). We retain these objects in our sample, since the contribution to the observed continuum by the AGN is not significant (see Section 3.2 below).

Baldwin, Phillips & Terlevich (1981, hereafter BPT) demonstrated that it was possible to distinguish type 2 AGNs from normal star-forming galaxies by considering the intensity ratios of two pairs of relatively strong emission lines, and this technique was refined by Veilleux & Osterbrock (1987). It has become standard practice to classify objects according to their position on the so-called BPT

Figure 1. An example of a BPT (Baldwin et al. 1981) diagram in which we plot the emission-line flux ratio $[O\text{ III}]\lambda 5007/H\beta$ versus the ratio $[N\text{ II}]/H\alpha$ for all the galaxies in our sample where all four lines are detected with $S/N > 3$ (55 757 objects). The dotted curve shows the demarcation between starburst galaxies and AGN defined by Kewley et al. (2001). The dashed curve shows our revised demarcation (equation 1). A total of 22 623 galaxies lie above the dashed curve. Seyfert galaxies are often defined to have $[O\text{ III}]/H\beta > 3$ and $[N\text{ II}]/H\alpha > 0.6$, and LINERs to have $[O\text{ III}]/H\beta < 3$ and $[N\text{ II}]/H\alpha > 0.6$. Our sample includes 2537 Seyferts and 10 489 LINERs according to this definition.

diagrams. Fig. 1 shows an example of such a diagram for all the emission-line galaxies in our sample. We have plotted the ratio $[\text{O III}] \lambda 5007/\text{H}\beta$ versus the ratio $[\text{N II}] \lambda 6583/\text{H}\alpha$ for all galaxies where all four lines were detected with signal-to-noise ratio $S/N > 3$. Note that these ratios are almost completely insensitive to reddening or to errors in the spectrophotometry. This sample includes 55 757 objects (45.4 per cent of our total sample of 122 808 galaxies). The other BPT diagrams involving the ratios $[\text{S II}] \lambda \lambda 6717, 6731/\text{H}\alpha$ and $[\text{OI}] \lambda 6300/\text{H}\alpha$ include a somewhat smaller fraction of objects at a similar cut in signal-to-noise ratio.

The exact demarcation between star-forming galaxies and AGN is subject to considerable uncertainty. Recently, Kewley et al. (2001) used a combination of photoionization and stellar population synthesis models to place a theoretical upper limit on the location of star-forming models in the BPT diagrams. Their models allow for a wide range in metallicity, ionization parameter and dust depletion, and also make allowances for the effects of shock excitation by supernovae. The Kewley et al. demarcation between starbursts and AGN (shown as the dotted line in Fig. 1) represents a very conservative *lower* limit on the true number of AGN in our sample. Galaxies with emission-line ratios that place them above this line cannot be explained by any possible combination of parameters in a star-forming model.

In practice, star-forming galaxies exhibit strong correlations between properties such as ionization parameter and metallicity, which cause them to exhibit rather little scatter around a single relation in the BPT diagram. This is evident from Fig. 1, which shows that there are two well-separated sequences of emission-line galaxies and that the AGN sequence separates from the sequence of star-forming galaxies well below the Kewley et al. (2001) demarcation curve. Based on these data, we have chosen to revise the demarcation between starburst galaxies and AGN as follows: a galaxy is defined to be an AGN if

$$\log([\text{O III}]/\text{H}\beta) > 0.61/[\log([\text{N II}]/\text{H}\alpha) - 0.05] + 1.3. \quad (1)$$

This curve is represented by the dashed line in Fig. 1, and, in what follows, we use this as our canonical division between star-forming galaxies and AGN in our sample.

Narrow-line (type 2) AGN are traditionally divided into three general classes: type 2 Seyfert galaxies, LINERs and the so-called ‘transition’ objects. LINERs (Heckman 1980b) typically have much lower nuclear luminosities than Seyfert galaxies. Spectroscopically, they resemble Seyferts except that low ionization lines such as $[\text{OI}] \lambda 6300$ and $[\text{N II}] \lambda \lambda 6548, 6583$ are relatively strong. The relationship of LINERs to the more powerful Seyferts and QSOs has been a topic of substantial controversy. Like the Seyferts, the emission-line properties of LINERs can be explained by ionization by a ‘hard’ power-law spectrum. LINER-type spectra can, however, also be produced in cooling flows, starburst-driven winds and shock-heated gas. This has led to some debate as to whether LINERs should be considered as a true low-luminosity extension of the AGN sequence. Finally, Ho, Filippenko & Sargent (1993) introduced a class of ‘transition’ objects with nuclear emission-line properties intermediate between those of normal star-forming galaxies and those of Seyferts and LINERs. Ho et al. proposed that these objects are in fact ordinary LINER/Seyfert galaxies whose integrated spectra are diluted or contaminated by neighbouring H II regions.

In traditional classification schemes (see for example Ho, Filippenko & Sargent 1997), Seyfert galaxies are identified as those objects with high values both of $[\text{O III}]/\text{H}\beta$ (> 3) and of other ratios involving lower ionization lines, such as $[\text{N II}]/\text{H}\alpha$, $[\text{S II}]/\text{H}\alpha$ and $[\text{OI}]/\text{H}\alpha$. LINERs, on the other hand, have lower values of

$[\text{O III}]/\text{H}\beta$ (< 3), but high values of ratios involving the lower ionization lines.

3.1 AGN as a sequence in $[\text{O III}]$ line luminosity

Contributions to the emission-line spectrum by both star formation and an AGN are almost inevitable in many of the SDSS galaxies, given the relatively large projected aperture size of the fibres (5.5 kpc diameter at $z = 0.1$). This is much larger than the ~ 200 pc apertures used in the survey of nearby galaxy nuclei by Ho et al. (1997). It is therefore not surprising that the majority of AGN in our sample fall into the ‘transition’ class, and have line ratios intermediate between those of star-forming galaxies and those of LINERs or Seyferts. We also find the fraction of AGN in the survey lying above the Kewley et al. (2001) demarcation line to be a strongly *decreasing* function of redshift. This is also consistent with our conjecture that the physical size of the aperture plays a critical role in determining whether or not an AGN falls into the transition class.

We therefore prefer an AGN classification system that is less sensitive to aperture, while still reflecting the difference in intrinsic nuclear luminosity between Seyfert galaxies and LINERs. Because we are studying type 2 systems, we seek an AGN component that emits radiation isotropically and that can be assumed to provide some indication of the total level of nuclear activity in the galaxy. In the optical, it is traditional to consider the luminosity of the narrow-line emission region (NLR), which, in principle, should not be strongly affected by the obscuring torus that surrounds the central source.

In this paper, we focus on the luminosity of the $[\text{O III}] \lambda 5007$ line as a tracer of AGN activity. Although this line can be excited by massive stars as well as an AGN, it is known to be relatively weak in metal-rich, star-forming galaxies. This can be seen in Fig. 1: star-forming galaxies define a sequence in which the ratio $[\text{O III}]/\text{H}\beta$ decreases and the ratio $[\text{N II}]/\text{H}\alpha$ increases towards higher gas-phase metallicities (e.g. Charlot & Longhetti 2001). The AGN sequence emerges as a plume from the bottom of the locus of star-forming galaxies. The morphology of the plume is strongly suggestive of a ‘mixing line’, in which the relative contribution of the AGN increases from lower left to upper right (see Kewley et al. 2001, for a discussion). Fig. 1 also suggests that the ‘contaminating’ emission is from metal-rich, star-forming regions, because the AGN sequence emerges from the bottom of the locus of star-forming galaxies. As we show later, this is expected because AGN are located in massive galaxies. Star-forming galaxies are known to exhibit a strong mass–metallicity relation (Tremonti et al. 2003). If AGN hosts lie on this relation, their metallicities will be solar or higher, and the contamination of the $[\text{O III}]$ line by star formation will be small.

The $[\text{O III}]$ line also has the advantage of being strong and easy to detect in most galaxies. It should be noted that, because the narrow-line emission arises outside the dust sublimation radius, it is affected by dust within the host galaxy. Thus it is important to correct our $[\text{O III}]$ luminosities for the effects of extinction. We can measure the extinction using the Balmer decrement. This procedure has clear physical meaning in the ‘pure’ type 2 Seyfert galaxies and LINERs. In the case of the transition objects, the lines will arise in both the NLR and the surrounding H II regions, with a greater relative AGN contribution to $[\text{O III}]$ than to the Balmer lines. Thus, a dust correction to $[\text{O III}]$ based on the ratio $\text{H}\alpha/\text{H}\beta$ should be regarded as at best approximate.

In Fig. 2 we plot the $[\text{O III}]/\text{H}\beta$ versus $[\text{N II}]/\text{H}\alpha$ BPT diagram in bins of extinction-corrected $[\text{O III}]$ line luminosity. Fig. 2 shows

Figure 2. The BPT diagram of Fig. 1 has been binned into fixed ranges in extinction-corrected [O III] line luminosity. Note that luminosities are given in units of the bolometric solar luminosity ($3.826 \times 10^{33} \text{ erg s}^{-1}$). The dashed curve shows our adopted demarcation between star-forming galaxies and AGN. The full curve shows the Kewley et al. (2001) demarcation. The dotted line marks the angle $\Phi = 25^\circ$, which separates pure LINERs from Seyferts reasonably cleanly.

clearly that the region of the BPT diagram occupied by galaxies classified as LINERs is primarily populated by objects with low [O III] line luminosities. Conversely, the region of the diagram with $[\text{O III}]/\text{H}\beta > 3$ and $[\text{N II}]/\text{H}\alpha > 0.6$ (i.e. the Seyfert region of the diagram) is mainly populated with galaxies that have high [O III] luminosities. This demonstrates that classification by line ratio and classification by [O III] luminosity are roughly equivalent for LINERs and Seyferts.

The virtue of classifying galaxies by [O III] luminosity is that this then allows us to study the large number of transition galaxies with spectra intermediate between pure star-forming systems and pure LINERs/Seyferts. Fig. 2 shows that transition galaxies span a wide range in [O III] luminosity, but have very similar line ratios. This means that one cannot distinguish between transition objects containing a Seyfert 2 nucleus and those containing a LINER on the basis of position in the BPT diagram alone. Adding the extra dimension of [O III] luminosity, the separation is clear. We stress that any attempt to characterize the stellar population in AGN hosts must include the transition objects that comprise the majority of the AGN in Fig. 1. Excluding these would bias the sample against host galaxies with significant amounts of on-going star formation.

We propose the following simple scheme for characterizing the position of an emission-line galaxy on the BPT diagram of Fig. 1. We define an ‘origin’ O located at $[\text{N II}]/\text{H}\alpha = -0.45$ and $[\text{O III}]/\text{H}\beta = -0.5$, i.e. near the bottom of the locus of star-forming galaxies where it intersects the lower end of the AGN sequence. We then parametrize the position of each galaxy by its distance D from the origin O, and by an angle Φ , which is defined to be zero in the direction parallel to the positive [O III]/Hβ axis, and which increases as the galaxy moves in a clockwise direction towards increasing values of $[\text{N II}]/\text{H}\alpha$ and decreasing values of $[\text{O III}]/\text{H}\beta$. In this scheme, pure

Seyferts are characterized by large values of D and small values of Φ (0° – 25°), whereas ‘pure’ LINERs are characterized by large values of D and values of Φ in the range 25° – 60° . Transition objects are characterized by small values of D .

The left panel of Fig. 3 shows the correlation between [O III] line luminosity and Φ for the AGN in our sample. In this plot, we have excluded the transition objects by selecting only those AGN that lie above the Kewley et al. (2001) demarcation curve. There is a strong transition in the median AGN luminosity at $\Phi \sim 25^\circ$. In the right panel of Fig. 3, we plot $L[\text{O III}]$ as a function of D . There is no strong trend in intrinsic AGN luminosity as a function of distance from the locus of star-forming galaxies. This supports the idea that

Figure 3. Left: The [O III] line luminosity is plotted as a function of the angle parameter Φ for all AGN lying above the Kewley et al. (2001) demarcation curve in Fig. 1. Right: The [O III] line luminosity is plotted as a function of D , the distance from the locus of star-forming galaxies. In each plot the solid line shows the median relation as a function of D or Φ , while the dashed and dotted lines indicate the 16–84 and 2.5–97.5 percentiles in $\log L[\text{O III}]$ respectively.

AGN define two basic ‘mixing sequences’: a star formation plus high-luminosity AGN (Seyfert 2 sequence) and star formation plus low-luminosity AGN (LINER sequence).

3.2 The effect of the AGN on the derived host galaxy properties

The traditional view of type 2 AGN is that their spectra are composed of an old, metal-rich stellar population plus an underlying ‘featureless continuum’ produced by the central source (e.g. Koski 1978). This view has been challenged in recent years by a number of studies showing that the spectra are, in fact, better fitted by stellar populations that span a wide range in age and metallicity.

Schmitt, Storchi-Bergmann & Cid Fernandes (1999) have carried out a detailed spectral synthesis analysis of spectra of the nuclear regions of 20 nearby type 2 Seyfert galaxies. They fitted each observed spectrum using a grid of equivalent widths and continuum ratios measured from star clusters of different ages and metallicities. In addition they included a $F_\nu \propto \nu^{-1.5}$ power-law component to represent a canonical AGN continuum. The code considers *all possible* linear combinations of age, metallicity and featureless continuum, weighting each solution by $e^{-\chi^2/2}$ in order to construct the likelihood function of parameters such as stellar age or fractional contribution of the AGN continuum. The main result of this analysis is that the continuum contribution of the AGN is extremely small, rarely exceeding 5 per cent. The analysis in Schmitt et al. (1999) focused on the nuclear stellar populations of type 2 Seyfert galaxies. As discussed in Section 2, the SDSS spectra include much more galaxy light, so we expect the contribution from the featureless continuum to be even smaller.

It is important to establish that this is the case. Throughout this paper we will use the strength of the 4000-Å break as our primary indicator of the age of the stellar population. Any contribution of AGN light would decrease the strength of the 4000-Å break, causing us to underestimate the age of the stellar population. It should be

noted, however, that stellar Balmer absorption lines become weaker with age, and for ‘well-behaved’ (continuous) past star-formation histories the equivalent widths of the Balmer lines are inversely correlated with the 4000-Å break strength (see Paper I). Thus, the addition of AGN light to the Balmer lines would cause us to *overestimate* the stellar age. A clear test of the importance of AGN light is to compare the Balmer absorption lines in AGN hosts with the Balmer lines in normal galaxies that have the same 4000-Å break strength. If AGN light is significant, the Balmer lines will be *weaker* in the AGN hosts.

To perform this test, we have combined the spectra of our highest [O III] luminosity AGN to create a high signal-to-noise ratio *composite* spectrum. This is plotted as the black line in Fig. 4. For each AGN included in the composite, we picked out a random galaxy from the parent sample with the same stellar mass, 4000-Å break strength and redshift as the AGN host. We combined the spectra of these ‘matching’ galaxies to create the spectrum shown in red. As can be seen, the AGN spectrum and the galaxy spectrum are identical except for the emission lines, which are stronger in the AGN (as expected). In particular, the high-order Balmer absorption lines match extremely well. We have also experimented with fitting the AGN template spectrum with a combination of BC03 model spectra and a canonical QSO spectrum (Vanden Berk et al. 2001). We find that we cannot obtain an acceptable fit if the QSO contributes more than a few per cent of the light in the *r* band.

It is also important to consider the effect of the AGN emission on the basic galaxy structural properties derived from the SDSS imaging data. In particular, we have used the *z*-band absolute magnitude to calculate the host galaxy stellar mass (M_*) and surface mass density (μ_*), and have used the *r*-band images to measure the concentration parameter (*C*). From Fig. 4, it is clear that the continuum in AGN hosts is dominated by starlight and that any AGN continuum emission will not affect our derived parameters. The effect of AGN emission lines will likewise be small. The *z* band samples a spectral region in the rest frame of a typical AGN host that is devoid of

Figure 4. A comparison of the stacked spectra of 500 AGN with [O III] line luminosities in the range 10^8 – 10^9 solar (black) with the stacked spectra of a set of matching galaxies (red). The blue line shows the residual when the galaxy spectrum is subtracted from the AGN spectrum.

strong emission lines. For $z \leq 0.06$ the [N II] $\lambda\lambda 6548, 6584$ and H α emission lines fall in the r bandpass, while the [O III] $\lambda\lambda 4959, 5007$ lines move in at $z \geq 0.11$. Fortunately, either set of lines has a combined equivalent width ranging from ~ 10 Å in weak AGN to ~ 100 Å in powerful AGN. Since the SDSS r bandpass is ~ 1400 Å wide, the flux contribution of the emission lines to the r -band flux will be at most a few per cent in the inner 3-arcsec region of the galaxy.

In this section, we have argued that AGN light does not contribute significantly to the continuum emission in type 2 AGN. Regions of star formation do, however, make a significant contribution to the emission-line spectra of the AGN in our sample, because of the large projected aperture size of the SDSS fibres. Because the two composite spectra plotted in Fig. 4 are matched in stellar mass and in mean stellar age, it is reasonable to assume that the galaxies included in the two samples have similar amounts of on-going star formation. Comparison of the emission-line properties of the two spectra demonstrates that in the AGN composite spectrum, star-forming regions contribute 50 per cent of the [O II] $\lambda 3727$ flux, 70 per cent of the H β flux, 65 per cent of the H α flux, and 45 per cent of the [N II] $\lambda 6584$ and [S II] $\lambda\lambda 6717, 6731$ flux. In contrast, star-forming regions contribute only 7 per cent of the [O III] $\lambda 5007$ flux. The [O III] $\lambda 5007$ line is clearly a far better measure of the AGN power than any of the other strong emission lines. Croom et al. (2002) reach qualitatively similar conclusions for low-redshift QSOs.

4 THE HOST GALAXIES OF TYPE 2 AGN

In this section we study the properties of the host galaxies of the AGN in our sample, including their stellar masses, their surface

mass densities and concentrations, and their mean stellar ages as measured by spectral indices such as the 4000-Å break strength.

Note that the AGN in our sample are drawn from an r -band-limited spectroscopic survey of galaxies. Galaxies of different luminosities can be seen to different distances before dropping out due to the selection limits of the survey. The volume V_{\max} within which a galaxy can be seen, and will be included in the sample, goes as the distance limit cubed, which results in the samples being dominated by intrinsically bright galaxies. Throughout this analysis, we will correct for this effect by giving each galaxy or AGN a weight equal to the inverse of its maximum visibility volume determined from the apparent magnitude limit of the survey (see Paper II for more details). All correlations we plot should then be appropriate for a volume-limited sample of galaxies and should no longer be affected by selection biases due to the criteria that define the main galaxy sample.

4.1 Stellar mass and aperture effects

As discussed in Section 3, our sample of emission-line galaxies includes 55 747 objects where the four emission lines, H α , [N II], [O III] and H β , are all detected with $S/N > 3$. In total, 40 per cent of these galaxies are classified as AGN, but this number is strongly dependent on host mass and, to a lesser extent, on morphological type. This is illustrated in Fig. 5. In the top panels, the dotted histogram shows the fraction of all galaxies that have emission lines as a function of $\log M_*$ and C . The dashed histogram shows the fraction of all galaxies that are classified as AGN. The solid histogram shows

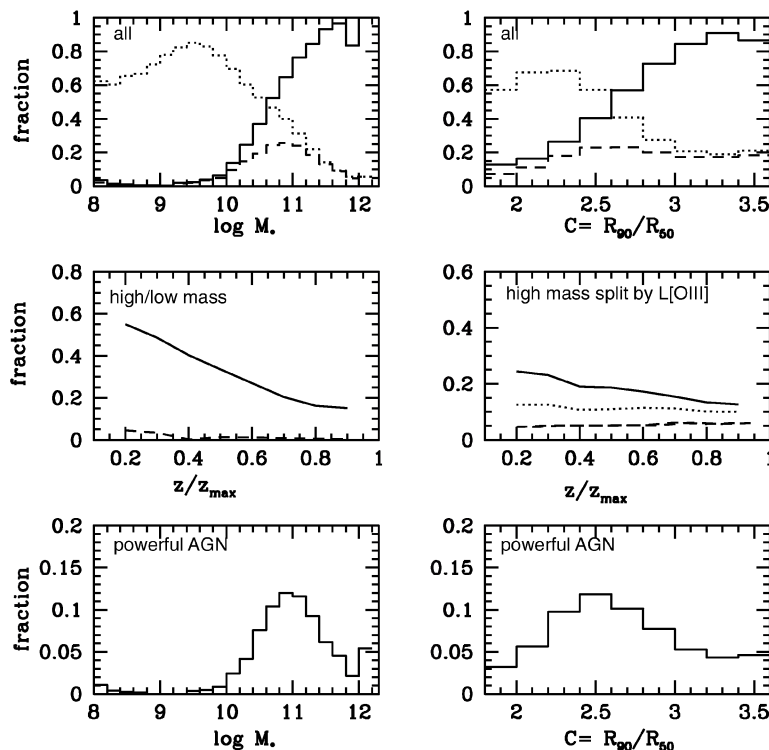

Figure 5. Top panels: The dotted histogram shows the fraction of all galaxies in our sample with $S/N > 3$ detections of [N II], H α , [O III] and H β as a function of $\log M_*$ and concentration index C . The dashed histogram shows the fraction of all galaxies classified as AGN. The solid histogram shows the fraction of emission-line galaxies classified as AGN. Middle left: The fraction of galaxies with $3 \times 10^{10} < M_* < 10^{11} M_\odot$ classified as AGN is plotted as a function of z/z_{\max} as a solid line. The dashed line is for galaxies with $3 \times 10^8 < M_* < 10^9 M_\odot$. Middle right: The AGN fraction for galaxies with $3 \times 10^{10} < M_* < 10^{11} M_\odot$ and with $\log L[\text{O III}] > 6.5$ (solid), 7 (dotted) and 7.5 (dashed) is plotted against z/z_{\max} . Bottom panels: The fraction of galaxies containing AGN with $\log L[\text{O III}] > 7$ is plotted as a function of $\log M_*$ and C .

the fraction of all *emission-line galaxies* that are classified as AGN. As can be seen, AGN are preferentially found in more massive and more concentrated galaxies. The dependence of AGN fraction on mass is very striking. Even though 70–80 per cent of galaxies with stellar masses less than $10^{10} M_{\odot}$ have detectable emission lines, only a few per cent are classified as AGN. In contrast, more than 80 per cent of emission-line galaxies with $M_{*} > 10^{11} M_{\odot}$ are AGN.

It should be noted that AGN detection rates are subject to strong selection effects. Ho et al. (1997) find that 43 per cent of the galaxies in their survey can be regarded as active and nearly all their galaxies have detectable emission lines. In our sample, the nuclear spectrum will be diluted by the light from the surrounding host galaxy, so our derived AGN fractions are lower. In the middle left panel of Fig. 5 we plot the AGN fraction as a function of normalized distance z/z_{\max} , where z_{\max} is the maximum redshift out to which the galaxy would have been included in the SDSS main galaxy sample. The solid line shows the AGN fraction for ‘massive’ galaxies with stellar masses in the range 3×10^{10} – $10^{11} M_{\odot}$. The dashed line is for low-mass galaxies in the range 10^8 – $3 \times 10^9 M_{\odot}$. The AGN fraction in massive galaxies is a very strong function of distance. At low values of z/z_{\max} , the AGN fraction reaches 50 per cent, a value very similar to the fraction that Ho et al. found for the L_{*} galaxies in their sample. On the other hand, the AGN fraction in low-mass galaxies does not rise above a few per cent, even at low values of z/z_{\max} . There are 6586 galaxies in our sample with stellar masses in the range 10^8 – $3 \times 10^9 M_{\odot}$, so this result has high statistical significance.

We now ask whether it is possible to define an AGN fraction that does not depend on aperture. In the middle right panel of Fig. 5, we plot the fraction of AGN in galaxies with stellar masses in the mass range 3×10^{10} – $10^{11} M_{\odot}$ and with [O III] line luminosities greater than 3×10^6 (solid), 10^7 (dotted) and $3 \times 10^7 L_{\odot}$ (dashed)

as a function of normalized distance. For [O III] luminosities greater than $10^7 L_{\odot}$, the AGN fraction no longer depends on z/z_{\max} . We will henceforth refer to AGN as ‘strong’ or ‘weak’ using $L[\text{O III}] = 10^7 L_{\odot}$ as a dividing line. Fig. 5 shows that our sample of strong AGN is complete. Figs 2 and 3 imply that the division very roughly corresponds to that between Seyferts and LINERs. Finally, in the bottom two panels of Fig. 5 we plot the fraction of ‘strong’ AGN in galaxies as a function of $\log M_{*}$ and C .

The most striking result in Fig. 5 is that very few AGN are found in galaxies with $M_{*} < 10^{10} M_{\odot}$. As discussed in Paper II, the majority of low-mass galaxies have young stellar populations and a significant fraction are experiencing ‘bursts’ of star formation at the present day. Many low-mass galaxies thus have strong emission lines due to star formation and one might therefore be concerned whether our BPT diagnostic method would be able to detect an AGN in such objects. In the top left panel of Fig. 6, we plot the [O III]/H β versus [N II]/H α BPT diagram for emission-line galaxies that are not classified as AGN and that have stellar masses in the range 10^8 – $3 \times 10^9 M_{\odot}$. The other three panels in Fig. 6 illustrate the effect of adding successively more powerful AGN to these galaxies. We have extracted ‘pure’ AGN lying above the Kewley et al. (2001) demarcation curve in Fig. 1 and we have ranked these AGN according to their extinction-corrected [O III] luminosities. For each low-mass galaxy, we select a random AGN and add its observed emission-line luminosities to those of the original galaxy. Fig. 6 shows that the presence of even a low-luminosity AGN with $10^5 < \log L[\text{O III}] < 10^6 L_{\odot}$ perturbs the emission-line ratios enough to allow the AGN to be identified in 93 per cent of the galaxies in the sample. The bottom right panel of Fig. 6 demonstrates that a powerful AGN with $L[\text{O III}] > 10^7 L_{\odot}$ would be detected in more than 99 per cent of the objects.

Figure 6. Top left: The BPT diagram of Fig. 1 for galaxies with $8 < \log M_{*} < 9.5$ that are not classified as AGN. Other three panels: The effect of adding AGN of increasing [O III] luminosity (see text for more details). The numbers in the upper right corners of each panel indicate the fraction of galaxies that lie above the dashed line.

Figure 7. Left: The distribution of stellar mass as a function of $[\text{O III}]$ luminosity for the AGN in our sample. The solid line shows the median value of $L[\text{O III}]$, while the dashed lines show the 16–84 percentiles of the $1/V_{\text{max}}$ weighted distribution. Right: The solid line shows the upper 97.5 percentile of the $[\text{O III}]$ distribution of all galaxies as a function of stellar mass. The dotted line is the upper 99 percentile.

Although we cannot rule out the presence of extremely weak active nuclei in low-mass galaxies, such as the AGN with $L[\text{O III}] = 5 \times 10^4 M_\odot$ discussed by Kraemer et al. (1999) in the Sdm galaxy NGC 4395, we conclude that more powerful AGN are confined almost exclusively to high-mass galaxies. Ulvestad & Ho (2002) have recently reached similar conclusions using radio observations of a sample of 40 late-type galaxies.

There are many studies in the literature that indicate a positive correlation between AGN power and host galaxy luminosity or linewidth. Most of these studies have been restricted to specific classes of AGN, for example Seyferts (e.g. Nelson & Whittle 1996), QSOs (e.g. Kotilainen & Ward 1994; Croom et al. 2002) and radio galaxies (e.g. Ledlow & Owen 1996). In the left panel of Fig. 7 we plot as a solid line the median stellar mass M_* of AGN host galaxies as a function of $[\text{O III}]$ luminosity. The dashed lines indicate the 16–84 percentiles of the M_* distribution at a given value of $L[\text{O III}]$. Fig. 7 shows that galaxies of given mass are able to host AGN that span a very wide (more than several orders of magnitude) range in $[\text{O III}]$ luminosity. Note that we are unable to detect AGN with $[\text{O III}]$ luminosities much below $10^4 L_\odot$, so the actual range may be considerably larger. The median stellar mass of the host depends only weakly on $[\text{O III}]$ luminosity, but we do find that more powerful AGN are located preferentially in more massive host galaxies.

In the right panel of Fig. 7, we plot the *maximum* $[\text{O III}]$ luminosity that is attained by galaxies of a given stellar mass. In order to estimate $L[\text{O III}](\text{max})$ in an unbiased way, we have ordered all 122 808 galaxies in our sample according to stellar mass. We then partition

the sample into mass bins that contain an equal number of galaxies (2000 in this case). The dotted line shows the upper 99th percentile of the $[\text{O III}]$ luminosity distribution in each mass bin. (Note that the most $[\text{O III}]$ -luminous galaxies are indeed AGN for $M_* > 10^{10} M_\odot$, but are mostly star-forming galaxies for $M_* < 10^{10} M_\odot$.) The solid line shows the upper 97.5 percentiles of the distribution. As can be seen, $L[\text{O III}](\text{max})$ scales roughly linearly with stellar mass at $10^{10} < M_* < 10^{11} M_\odot$. At high stellar masses $L[\text{O III}](\text{max})$ flattens and there is even evidence for a turnover at the highest masses ($M_* > 3 \times 10^{11} M_\odot$).

4.2 Surface mass density and concentration

Most previous studies of the global morphologies of type 2 AGN hosts have concentrated on Hubble type. Early morphological studies of Seyfert galaxies by Adams (1977) and Heckman (1978) revealed that most Seyferts are in spiral galaxies, primarily early-type spirals (Sa–Sb). AGN in the survey of nearby galaxy nuclei by Ho et al. (1997) are found in ellipticals, in lenticulars and in bulge-dominated spirals, with LINERs occupying earlier-type hosts than Seyferts or transition systems.

Because it is impracticable to classify hundreds of thousands of galaxies by eye, studies of galaxy morphology in the SDSS have focused on simple structural parameters that can be measured automatically for very large numbers of objects. In Section 2, we defined two such parameters: the concentration index C and the stellar surface mass density μ_* . As discussed in Strateva et al. (2001) and in

Figure 8. The stellar surface density μ_* and concentration index C are plotted as functions of $\log L[\text{O III}]$ for the AGN in our sample. The solid line shows the median, while the dashed lines indicate the 16–84 percentiles of the $1/V_{\text{max}}$ weighted distribution.

Paper II, early-type galaxies (Hubble type Sa, S0 and E) have μ_* in the range $3 \times 10^8 - 3 \times 10^9 \text{ M}_\odot \text{ kpc}^{-2}$ and $C > 2.6$. Late-type galaxies have $\mu_* < 3 \times 10^8 \text{ M}_\odot \text{ kpc}^{-2}$ and $C < 2.6$.

In Fig. 8 we plot the $1/V_{\text{max}}$ weighted distributions of μ_* and C as a function of [O III] luminosity for the AGN in our sample. AGN of all luminosities are found in galaxies with high surface densities and intermediate concentrations.

In Paper II, we showed that C and μ_* correlate strongly with stellar mass in ordinary galaxies. A sharp transition in both M_* and C takes place at a characteristic stellar mass of $\sim 3 \times 10^{10} \text{ M}_\odot$. If the sample is split into early- and late-type subsamples at a C index value of 2.6, the surface densities of late-type galaxies scale with stellar mass as $\mu_* \propto M_*^{5/3}$. The surface densities of early-type

galaxies, on the other hand, are independent of stellar mass, and have a median value of $10^9 \text{ M}_\odot \text{ kpc}^{-2}$.

Fig. 9 compares the μ_* versus M_* and the C versus M_* relations for AGN with those of ordinary galaxies. The grey-scale indicates the fraction of galaxies in a given logarithmic mass bin that fall into each bin in surface density or concentration (see Paper II for more details on how these conditional density distributions are computed). Note that we only plot the relations in mass bins that contain more than 100 objects. This is why the relations cut off below $10^{10}(10^{9.5}) \text{ M}_\odot$ for the strong (weak) AGN. Fig. 9 shows that strong AGN (defined to have $\log L[\text{O III}] > 7.0$) show very little dependence of either concentration or surface mass density on stellar mass. At all masses, they have the high densities typical of early-type galaxies and

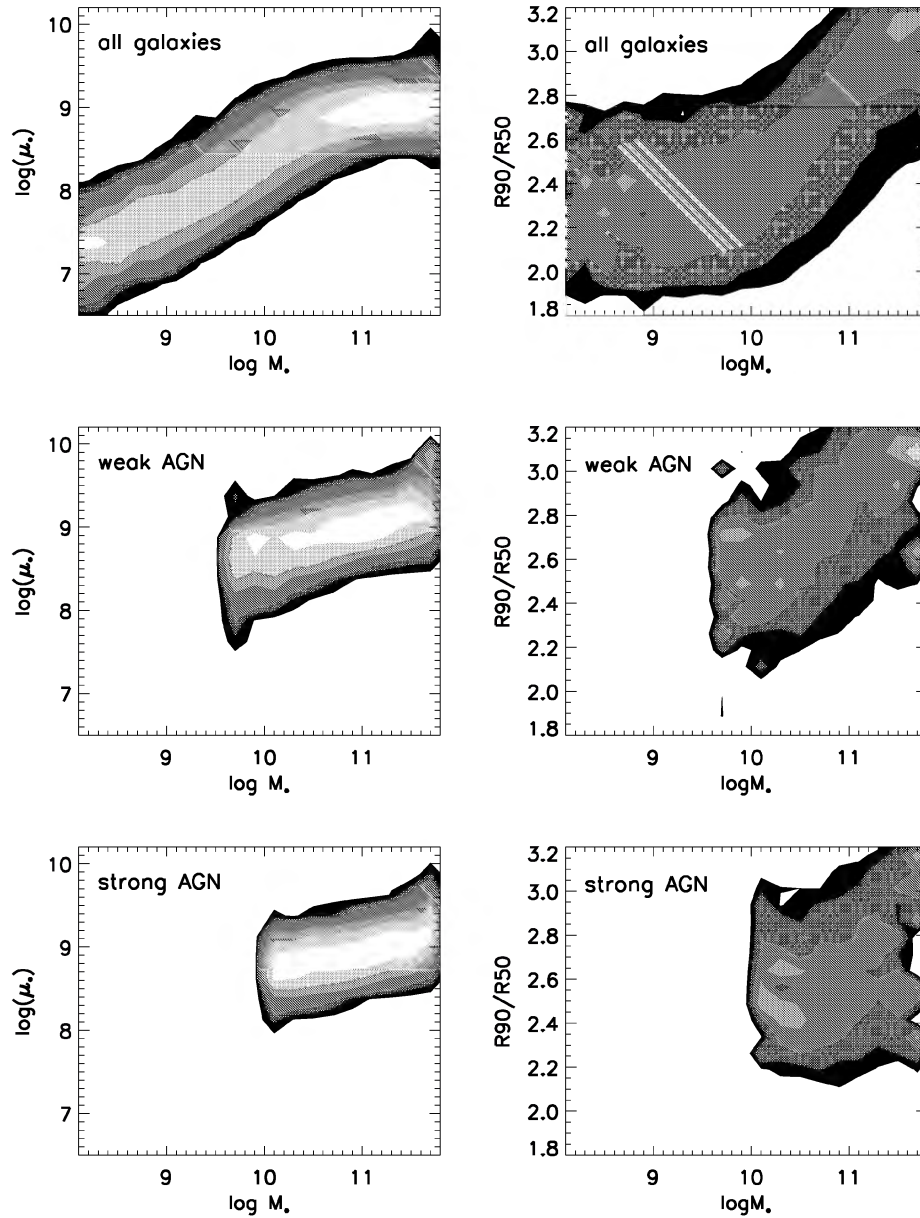

Figure 9. Left: Conditional density distributions showing trends in the surface mass density μ_* as a function of stellar mass M_* for all galaxies (top), for weak AGN with $\log L[\text{O III}] < 7.0$ (middle) and for strong AGN with $\log L[\text{O III}] > 7.0$ (bottom). Each object has been weighted by $1/V_{\text{max}}$ and the bivariate distribution has been normalized to a fixed number of galaxies in each bin of $\log M_*$. Right: Conditional density distributions showing trends in concentration index C as a function of $\log M_*$. In this and all other conditional density plots, each contour represents a factor of 2 increase in density.

Figure 10. The surface mass density distributions of the host galaxies of weak AGN (solid black histogram) and of strong AGN (dashed black histogram) are compared to those of early-type ($C > 2.6$) galaxies (solid curve) and late-type ($C < 2.6$) galaxies (dotted curve) in four separate ranges of $\log M_*$. The numbers listed in the top right corner of each panel indicate the percentage of galaxies in that mass range that are early type.

Figure 11. Trends in the μ_* versus M_* and the C versus M_* relations for AGN hosts as a function of angle parameter Φ and distance D from the locus of star-forming galaxies. Thick solid and dashed lines show the median relations for ordinary late- and early-type galaxies, respectively. The thinner line types are solid, dashed, dashed-dotted and dotted in order of decreasing Φ (top) and decreasing D (bottom).

Figure 12. $D_n(4000)$ and $H\delta_A$ are plotted as a function of $\log L[\text{O III}]$. The solid line shows the median, while the dashed lines indicate the 16–84 percentiles of the $1/V_{\text{max}}$ weighted distribution.

concentrations that are intermediate between early- and late-type galaxies. Both the concentrations and the surface densities of the weak AGN ($\log L[\text{O III}] < 7.0$) are similar to those of ordinary galaxies of the same stellar mass.

In Fig. 10, we compare the surface mass density distributions of AGN hosts to those of ordinary early-type and late-type galaxies. We have separated early-type galaxies from late types at a C index of 2.6, and we show results for four independent ranges in $\log M_*$. Fig. 10 shows that the surface density distributions of AGN host galaxies strongly resemble those of early-type galaxies of the same stellar mass.

Finally, Fig. 11 shows how the surface densities and concentrations of AGN hosts vary as a function of position on the BPT diagram. AGN that lie close to the sequence of star-forming galaxies

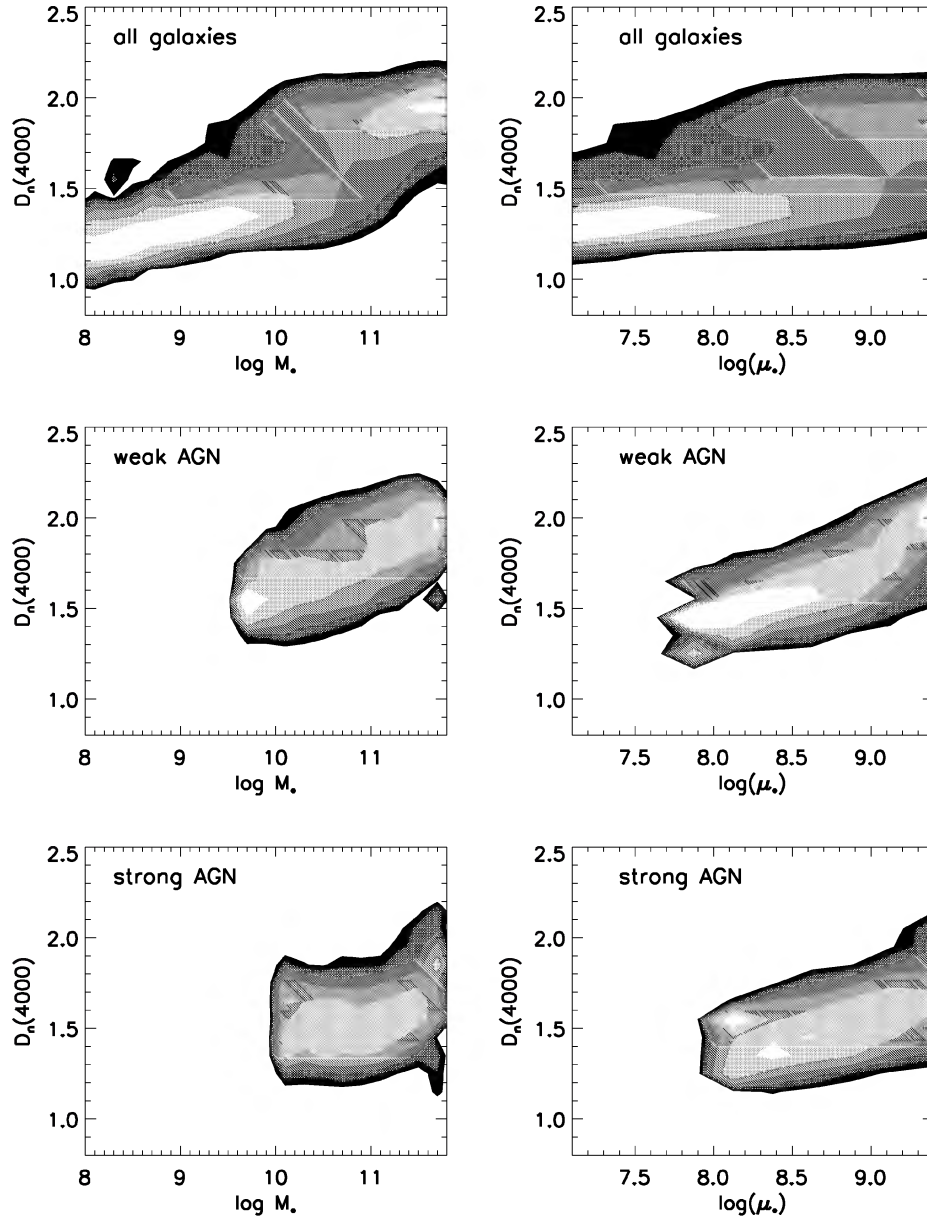

Figure 13. Conditional density distributions showing trends in $D_n(4000)$ as a function of stellar mass M_* and surface density μ_* for ordinary galaxies (top), weak AGN with $\log L[\text{O III}] < 7.0$ (middle) and strong AGN with $\log L[\text{O III}] > 7.0$ (bottom).

Figure 14. Top: The $D_n(4000)$ distribution for the host galaxies of weak AGN with $\log L[\text{O III}] < 7.0$ (black histogram) is compared to those for early-type ($C > 2.6$) galaxies (solid curve) and late-type ($C < 2.6$) galaxies (dotted curve) in two separate ranges of $\log M_*$. Bottom: The same, except for strong AGN with $\log L[\text{O III}] > 7.0$.

Figure 15. The thick black lines show the median relation between $D_n(4000)$ and $\log \mu_*$ for normal galaxies in two different ranges in stellar mass. The thin lines show the median relation for the host galaxies of AGN with $\log L[\text{O III}] < 6.0$ (solid), $6.0 < \log L[\text{O III}] < 7.0$ (short-dashed), $7.0 < \log L[\text{O III}] < 8.0$ (long-dashed) and $\log L[\text{O III}] > 8.0$ (dotted).

in the BPT diagram occur in lower-density, less-concentrated hosts. This is consistent with the idea that the transition objects occur in galaxies of later type than ‘pure’ Seyferts or LINERs. On the other hand, there appears to be rather little trend in the μ_* versus M_* or the C versus M_* relations as a function of the ionization-sensitive angle parameter Φ . [Note that in the Φ plots we have restricted the sample to objects lying above the Kewley et al. (2001) line, whereas in the D plots we use all objects above our canonical AGN line.] This result indicates that pure LINERs and pure Seyferts are structurally very similar.

4.3 Mean stellar age

In the previous subsection, we showed that AGN occupy host galaxies with structural properties similar to ordinary early-type galaxies (with the similarity being stronger for the weak AGN). The properties of the stellar populations of normal galaxies are known to correlate strongly with morphological type. Early-type galaxies have old stellar populations and very little gas and dust, whereas there is usually plenty of on-going star formation in late-type galaxies. As discussed in Paper I, $D_n(4000)$ is an excellent age indicator at mean stellar ages less than ~ 1 Gyr (corresponding to values $D_n(4000) < 1.4$ – 1.5). At older ages, the $D_n(4000)$ index is sensitive to metallicity as well as to age. We have shown that AGN are found in massive ($> 10^{10} M_\odot$) host galaxies, so metallicity variations among hosts are likely to be small and it is appropriate to use the $D_n(4000)$ index as a rough stellar age indicator.

In Fig. 12 we plot $D_n(4000)$ and $H\delta_A$ as functions of $[\text{O III}]$ luminosity for all the AGN in our sample. There is a strong correlation of both age-sensitive parameters with AGN luminosity. Only the weakest AGN have stellar ages in the range that is normal for early-type galaxies ($D_n(4000) > 1.7$ and $H\delta_A < 1$).

In Fig. 13, we compare the $D_n(4000)$ –stellar mass and $D_n(4000)$ –surface density relations for AGN hosts with those of normal galaxies. The normal galaxy relations exhibit a strong transition in $D_n(4000)$ at $M_* \sim 3 \times 10^{10} M_\odot$ and $\mu_* \sim 3 \times 10^8 M_\odot \text{ kpc}^{-2}$. This reflects a switch from a population of young late-type galaxies with low masses and low surface densities to a population of old early-type galaxies with high masses and high surface densities.

Fig. 13 shows that strong AGN do not fit on the relations defined by normal galaxies. They have a much weaker dependence of age on stellar mass or surface mass density than normal galaxies. In particular, they occur at much lower values of $D_n(4000)$ than the normal galaxies in the high-mass, high-density regime ($M_* > 3 \times 10^{10} M_\odot$, $\mu_* > 3 \times 10^8 M_\odot \text{ kpc}^{-2}$). The weak AGN resemble normal galaxies more closely.

In Fig. 14, we compare the $D_n(4000)$ distributions of AGN hosts with ‘normal’ early-type ($C > 2.6$) and late-type ($C < 2.6$) galax-

ies. This plot is very similar in spirit to Fig. 10, but reaches a rather different conclusion. In Fig. 10, we showed that *both* weak and strong AGN had surface density distributions very similar to early-type galaxies. Fig. 14 shows that the $D_n(4000)$ distributions of weak AGN resemble those of early types, but that strong AGN have stellar ages similar to those of late-type galaxies.

As discussed in Paper II, the star formation histories of normal galaxies appear to be more fundamentally linked to surface mass density than to mass. We demonstrated that there is a ‘universal’

Figure 16. $D_n(4000)$ is plotted as a function of Φ [for AGN lying above the Kewley et al. (2001) line] and D for weak AGN (solid) and for strong AGN (dashed). The thick lines indicate the median and the thin lines the 16–84 percentiles of the $1/V_{\text{max}}$ weighted distribution.

Figure 17. High S/N subsamples of normal galaxies, strong AGN and weak AGN are plotted in the $D_n(4000)/H + \delta_A$ plane. The locus occupied by galaxies with continuous star formation histories is indicated using coloured symbols. Red symbols are for solar metallicity models and magenta symbols indicate models with twice solar metallicity. The average error bar on the indices is shown in the corner of each panel.

relation between $D_n(4000)$ and μ_* that is independent of the stellar mass of the galaxy, except at the very highest values of M_* . The results in Fig. 14 suggest that the $D_n(4000)$ versus μ_* relation for the hosts of strong AGN is significantly different. In Fig. 15, we plot the median value of $D_n(4000)$ as a function of $\log \mu_*$ for AGN of different luminosities (thin lines) and compare this with the relation obtained for ordinary galaxies (thick black line). At high surface mass densities, low-luminosity AGN follow the relation defined by ordinary galaxies, but high-luminosity AGN have substantially smaller $D_n(4000)$ values (a younger age) at a given value of μ_* . At low surface mass densities, the hosts of weak AGN have older stellar populations than normal galaxies of the same surface density.

How can we reconcile the results of Fig. 15 with the fact that the majority of galaxies exhibit a very different relation between age and surface mass density? One interpretation is that powerful AGN reside in early-type galaxies that are undergoing or have recently undergone a transient star-forming event (starburst). The magnitude of this event might plausibly scale with AGN luminosity, so that its effects on the stellar population and structural parameters are most pronounced in the hosts of strong AGN. The duration of this event is short compared to the age of the Universe, so only a fraction of galaxies are caught in the act. As the AGN switches off and the stellar population ages, the galaxy eventually (re)joins the ranks of the normal early-type population. If this hypothesis is correct, then we ought to see evidence that the star formation time-scales in high-luminosity AGN are short.

In Fig. 16, we show the relation between $D_n(4000)$ and the position of the galaxy in the BPT diagram. Because $D_n(4000)$ is itself very strongly correlated with [O III] luminosity (Fig. 12), we remove this effect by analysing weak AGN and strong AGN separately. The left panel of Fig. 16 shows that there is then no residual correlation of $D_n(4000)$ with Φ . The correlation of $D_n(4000)$ with distance parameter D is more interesting. The right panel of Fig. 16 shows that, in weak AGN, $D_n(4000)$ correlates strongly with D , but in strong AGN, the dependence is much weaker. So far we have interpreted D as a measure of the relative contribution of star formation to the observed emission lines. (Recall that we showed in Fig. 3 that AGN luminosity does not correlate with D , implying that galaxies with lower values of D have relatively more star formation). For weak AGN, the increase in $D_n(4000)$ with distance from the locus of star-forming galaxies appears to support this hypothesis, but how can we explain the fact that there is a much weaker trend for strong AGN? The parameter D is determined by the amount of on-going star formation in the galaxy because the Balmer emission lines are excited by O stars with lifetimes of several million years. $D_n(4000)$, on the other hand, tracks the luminosity-weighted mean stellar age on much longer time-scales ($\geq 10^8$ yr). Thus, the result in Fig. 16 can be understood if high-luminosity AGN with young stellar populations, i.e. small $D_n(4000)$, and large D have recently stopped forming stars (i.e. they are *post-starburst* systems). In the next section, we demonstrate that this is indeed the case.

4.4 The star formation histories of AGN

Strong H δ absorption arises in galaxies that experienced a burst of star formation that ended 0.1–1 Gyr ago. As discussed in Papers I and II, the location of galaxies in the $D_n(4000)$ /H δ_A plane is a powerful diagnostic of whether they have been forming stars continuously or in bursts over the past 1–2 Gyr. Galaxies with continuous star formation histories occupy a very narrow strip in this plane. A recent burst is *required* in order to obtain significant displacement away from this locus. In Paper II, we also showed that the probability for a

Figure 18. The fraction F of AGN with $H\delta_A$ values that are displaced by more than 3σ above the locus of star-forming galaxies is plotted as a function of $\log L[\text{O III}]$. The dashed line indicates the fraction of such systems in the subsample of normal massive galaxies. The dotted line indicates the fraction of such systems in the subsample of normal massive galaxies with $D_n(4000) < 1.6$.

Figure 19. AGN are plotted in the $D_n(4000)/H\delta_A$ plane and are colour-coded according to the value of D , the distance from the locus of star-forming galaxies. Blue is for $D < 0.6$ and red is for $D > 0.6$.

galaxy to have experienced a recent burst is a strong function of stellar mass. A significant fraction (more than 10 per cent) of low-mass galaxies with $M_* \sim 10^8 M_\odot$ appear to have experienced recent bursts. The fraction of bursty galaxies drops by more than a factor of 10 for galaxies more massive than $10^{10} M_\odot$. In the previous section, we showed that the host galaxies of powerful AGN had mean stellar ages that were similar to those of ordinary late-type galaxies. In this section, we ask whether the star formation histories of AGN hosts are different from those of ordinary galaxies. In particular, we ask whether there is any evidence that powerful AGN are associated with bursty rather than continuous star formation histories.

In the SDSS sample, the typical error on the $H\delta_A$ index is 1.4 \AA , which is large compared to the total range of values spanned by this

index (-3 to $+9$ Å). In order to analyse the star formation histories of AGN in a more reliable way, we have extracted a subsample of objects with small (<0.5 Å) errors in $H\delta_A$. This reduces our total sample of AGN to 1400 objects. Compared to the full sample of 22 000 AGN, our subsample is biased to lower mean redshift (0.05 rather than 0.1). Thus, the spectra sample systematically smaller regions of the host galaxies than in the full sample (typical projected fibre diameter ~ 3 kpc versus ~ 6 kpc). However, so long as we impose the same selection criterion on the normal galaxies as we do on the AGN, the comparison between the two subsamples is a fair one.

In Fig. 17, we plot our subsamples of normal galaxies, strong AGN and weak AGN in the $D_n(4000)/H\delta_A$ plane. The locus occupied by galaxies with continuous star formation histories is indicated using red and magenta coloured symbols. The normal galaxies are selected to have stellar masses in the same range as the AGN hosts (10^{10} – $5 \times 10^{11} M_\odot$). As can be seen, most normal galaxies fall close to the locus of continuous star formation histories. A significant fraction of the powerful AGN, on the other hand, are displaced to high values of $H\delta_A$. This is shown quantitatively in Fig. 18, where we plot the fraction F of AGN with $H\delta_A$ values that are displaced by more than 3σ above the locus of continuous models. This fraction increases from several per cent for the weakest AGN to nearly a quarter for the strongest. The corresponding value of F for the sample of normal massive galaxies is only 0.07. For normal massive galaxies with ‘young’ stellar populations, i.e. $D_n(4000) < 1.6$, we have $F = 0.12$.

In Fig. 19, we colour-code the AGN according to D , the distance from the locus of star-forming galaxies in the BPT diagram. AGN that lie close to the star-forming locus are coloured blue, while those that lie far away are coloured red. Nearly all the weak AGN with large values of D have large values of $D_n(4000)$. Most of the strong AGN with large values of D have higher-than-normal values of $H\delta_A$. This lends further credence to our hypothesis that the latter objects are post-starburst systems; they experienced a burst some time in the past and are now evolving towards the locus occupied by ordinary early-type galaxies.

4.5 Radial distribution of the star formation

Most previous studies of the stellar populations of type 2 AGN hosts have focused on the *nuclear regions* of the host galaxies (see Heckman 2003, for a recent review). The stellar populations in the nuclei of weak AGN are predominantly old (e.g. Ho et al. 2003), while a young stellar population is clearly present in about half of powerful type 2 Seyfert nuclei (e.g. Cid Fernandes et al. 2001; Joguet et al. 2001). We obtain qualitatively similar trends in mean stellar age as a function of AGN luminosity, but we find that there are young stars in most AGN with [O III] luminosities greater than $10^7 L_\odot$. One might thus speculate that there might be systematic radial gradients in the stellar populations of the host galaxies of these systems.

We can test this by splitting our sample into different bins in normalized distance z/z_{\max} . We then find that there are rather strong radial gradients in mean stellar age and that the youngest stars appear to be located well *outside* the nuclei of the host galaxies. This is illustrated in Fig. 20. We have selected AGN with [O III] luminosities in excess of $3 \times 10^7 L_\odot$ and we plot the locations of the host galaxies in the $C/D_n(4000)$ plane. The left panel shows objects with $z/z_{\max} > 0.8$. These galaxies have redshifts in the range 0.1–0.2 and the spectra sample between 40 and 60 per cent of the total light. As can be seen, the vast majority of these objects have $D_n(4000)$ values less than 1.6 and are hence younger than the typical early-type galaxy

Figure 20. AGN with [O III] luminosities greater than $10^{7.5} L_\odot$ are plotted in the $D_n(4000)/C$ plane. In the left panel we show objects with $z/z_{\max} > 0.8$. In the right panel, we show objects with $z/z_{\max} < 0.3$.

in our sample. The right panel shows objects with $z/z_{\max} < 0.3$. These galaxies have typical redshifts of 0.03–0.04 and the spectra sample the light from the inner 1–2 kpc of the host galaxy. As can be seen, more than half the galaxies now have $D_n(4000) > 1.6$. The shift in mean stellar age occurs both in late-type ($C < 2.6$) and in early-type ($C > 2.6$) AGN hosts. We conclude the star formation associated with AGN activity is not primarily confined to the nuclear regions of the host galaxy.

4.6 Dust

As discussed in Section 3, we correct the [O III] luminosities of the AGN in our sample for dust using the difference between the observed $H\alpha/H\beta$ emission-line flux ratios and the case-B recombination value (2.86). We assumed an attenuation law of the form $\tau_\lambda \propto \lambda^{-0.7}$ (Charlot & Fall 2000). In the top right panel of Fig. 21, we plot the average attenuation at [O III] $\lambda 5007$ as a function of normalized AGN luminosity. As can be seen, the correction is very small for weak AGN, but rises strongly with increasing $L[\text{O III}]$, and reaches 2.5–3 magnitudes for the most powerful AGN. This is as expected, since weak AGN have old stellar populations (thus, little dust), whereas strong AGN have young stellar populations (more dust). Is three magnitudes of extinction at [O III] a reasonable value for the strong AGN? Dahari & De Robertis (1988) have tabulated the Balmer decrements of 64 type 2 Seyfert nuclei, and the implied mean [O III] attenuation is ~ 2.5 magnitudes. This is similar to what we measure through much larger physical apertures. In the left panel of Fig. 21, we plot the attenuation as a function of stellar mass for normal emission-line galaxies in our sample. The average value of the attenuation at 5007 Å for massive (more than a few times $10^{10} M_\odot$) star-forming galaxies is the same as that for the powerful AGN in our sample. These comparisons give us confidence that our average dust corrections are appropriate.

In the bottom panels of Fig. 21, we plot the attenuation in AGN hosts as a function of $D_n(4000)$ and D . There is a clear connection between star formation and extinction in AGN hosts, with younger, i.e. low $D_n(4000)$, and more strongly star-forming, i.e. low D , galaxies exhibiting more attenuation due to dust.

5 COMPARISON OF TYPE 2 AGN AND QSO HOSTS

We have shown that powerful type 2 AGN reside in massive galaxies with young stellar populations. So far, we have not considered type 1 Seyfert nuclei and QSOs because their optical continuum is primarily produced by the AGN (rather than by stars).

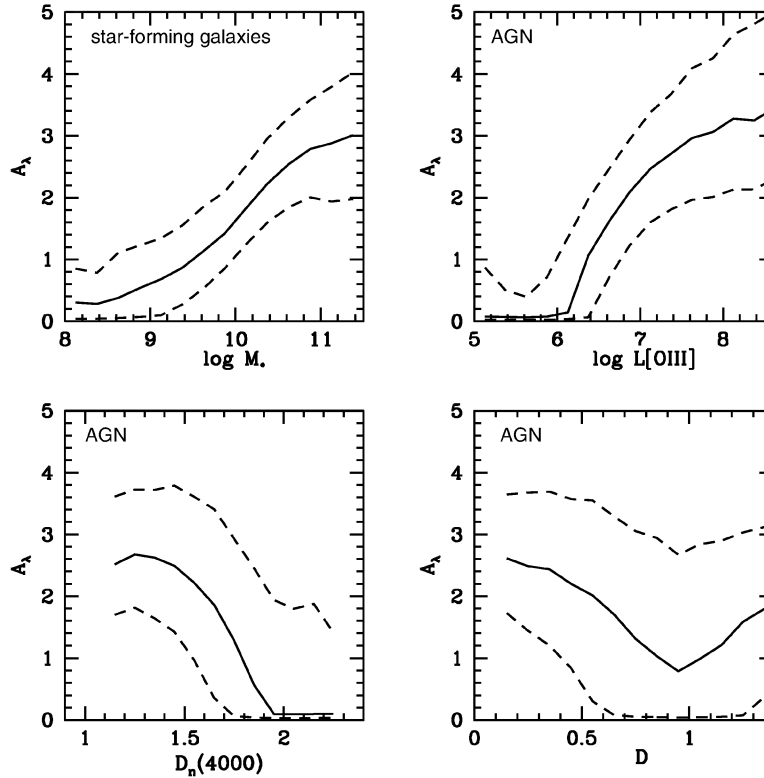

Figure 21. Top left: The attenuation at [O III] $\lambda 5007$ in magnitudes is plotted as a function of stellar mass for normal star-forming galaxies. Top right: The attenuation is plotted as a function of [O III] luminosity for AGN. Bottom: Attenuation in AGN hosts is plotted as a function of $D_n(4000)$ (left) and distance parameter D (right). The solid line shows the median value of the attenuation, while the dashed lines show the 16–84 percentiles of the $1/V_{\max}$ weighted distribution.

In the simplest version of the ‘unified’ model (Antonucci 1993), type 1 and type 2 AGN are drawn from the same parent population and differ only in our viewing angle with respect to a circumnuclear obscuring medium. In this case, the stellar contents of the two types should be the same. On the other hand, if the solid angle covered by the obscuring medium varies substantially from one system to another, then the type 2 AGN would be preferentially drawn from the more obscured systems. In this case, there could be systematic differences in stellar content between type 1 and type 2 AGN, since the covering factor of the dusty material might be related to the amount of star formation in the galaxy. There have been suggestions that this effect is present in Seyfert galaxies (e.g. Maiolino et al. 1995; Malkan et al. 1998; Oliva et al. 1999). Dunlop et al. (2001) have argued that powerful low-redshift QSOs are hosted by relatively normal old massive elliptical galaxies. This would make them fundamentally different from the hosts of powerful type 2 AGN.

In this section, we compare the stellar populations of the hosts of powerful type 1 and type 2 AGN using our present sample and a comparison sample drawn from a sample of powerful type 1 AGN (hereafter, QSOs) that we extracted directly from the Sloan Survey itself. The sample consists of objects with spectra that were classified as QSOs either by the SPECTRO1D pipeline, or by the spectral classification algorithm designed by D. Schlegel. We found that the two classification algorithms returned a rather different sample of objects – the Schlegel sample contained a larger number of faint AGN. In view of this, we decided to impose a number of additional cuts on the data. Specifically, we required all the QSOs in our sample to have Balmer linewidths larger than 500 km s^{-1} and equivalent widths in the broad component of the $H\alpha$ line of

20 \AA or greater. We then visually inspected the spectra of all the objects in our sample and found that these cuts resulted in a sample with only a 1–2 per cent contamination by type 2 AGN. Finally, we selected all QSOs having $0.05 \leq z \leq 0.2$ and $L[\text{O III}] \geq 10^{41} \text{ erg s}^{-1}$. These selection criteria on redshift and [O III] luminosity are designed to maximize the overlap with the powerful type 2 AGN population of our sample. Our final sample consists of 367 QSOs.

For each QSO, we search for a type 2 AGN with a similar redshift and [O III] luminosity. We were able to find a good match for 336 out of the 367 objects in our sample. The median [O III] luminosity is $10^{41.3} \text{ erg s}^{-1}$. The median absolute magnitude of the QSO sample is $M_r = -21.7$, or about one magnitude fainter than the corresponding value for the radio-quiet QSOs studied by Dunlop et al. (2001).

The individual flux-calibrated spectra were normalized at 5500 \AA and combined with no additional weighting. The results are shown in black (QSOs) and in red (matched type 2 AGNs) in the top panel of Fig. 22. For comparison, we plot in blue the composite spectrum of 60 of the QSOs in our sample with the highest *continuum*

¹ It is very difficult to correct the [O III] luminosities of QSOs for extinction, because the Balmer lines are dominated by emission from the broad-line region. We have therefore chosen to match the type 2 AGN and QSOs in terms of their observed [O III] line luminosities. We thus neglect any differences in extinction between the two kinds of objects. For reference, the median extinction-corrected [O III] luminosity for the 449 type 2 AGN is $10^{42.1} \text{ erg s}^{-1} = 10^{8.5} L_{\odot}$. These are among the most powerful AGN in our sample.

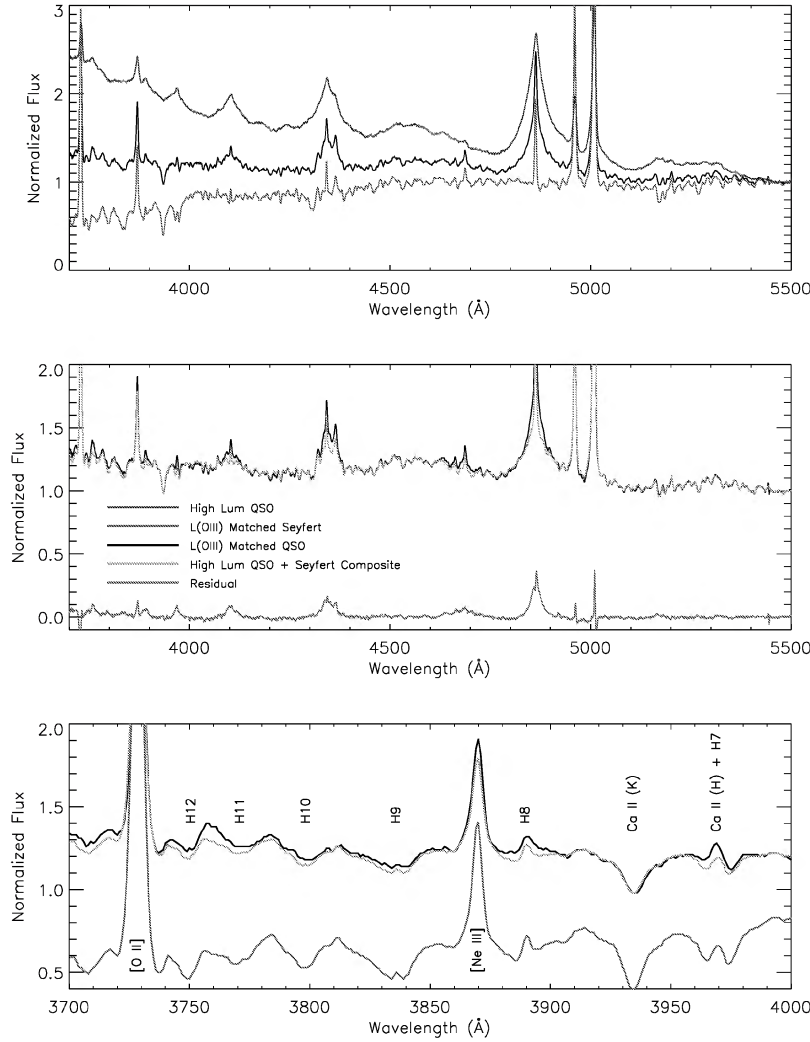

Figure 22. Top: The composite type 2 AGN spectrum is shown in red. The composite spectrum of matched QSOs is shown in black. A composite spectrum of QSOs with very high continuum luminosities is shown in blue. Middle: A linear combination of 62 per cent type 2 AGN plus 38 per cent pure QSO (green) is compared to the matched QSO spectrum (black). The residual is shown in purple. Bottom: The spectral region between 3700 and 4000 Å is shown in more detail. The main stellar absorption lines, including the higher-order Balmer lines and calcium H + K lines, have been marked for clarity.

luminosities at 5007 Å and with $0.1 < z < 0.35$. We will refer to this composite as the ‘pure QSO’ spectrum.

As can be seen, the stellar absorption features in the matched QSO spectrum are weaker than in the type 2 AGN spectrum. This is expected, because a substantial fraction of the continuum in the matched QSO spectrum is coming from a central nuclear source rather than from stars. This is illustrated in detail in the central panel of Fig. 22, where we plot in green the linear combination of the type 2 AGN plus pure QSO spectra that produces the best fit to the matched QSO spectrum. We find a very good overall fit if 38 per cent of the continuum at 5500 Å comes from a pure QSO. The main residuals are located around the broad emission-line features, which show substantial variations from one QSO to another. In the bottom panel of Fig. 22, we show a blow-up of the region of the spectrum between 3700 and 4000 Å. We have labelled the main stellar absorption-line features (these include a series of high-order Balmer lines and the calcium H + K feature). It is clear that the stellar absorption spectra are virtually identical in type 2 AGNs and in the matched QSOs.

Figure 23. The observed continuum luminosity at 5007 Å (in units of $\text{erg s}^{-1} \text{Å}^{-1}$) is plotted as a function of [O III] line luminosity (in units of erg s^{-1}) for QSOs with $z < 0.8$ in the SDSS DR1 QSO catalogue.

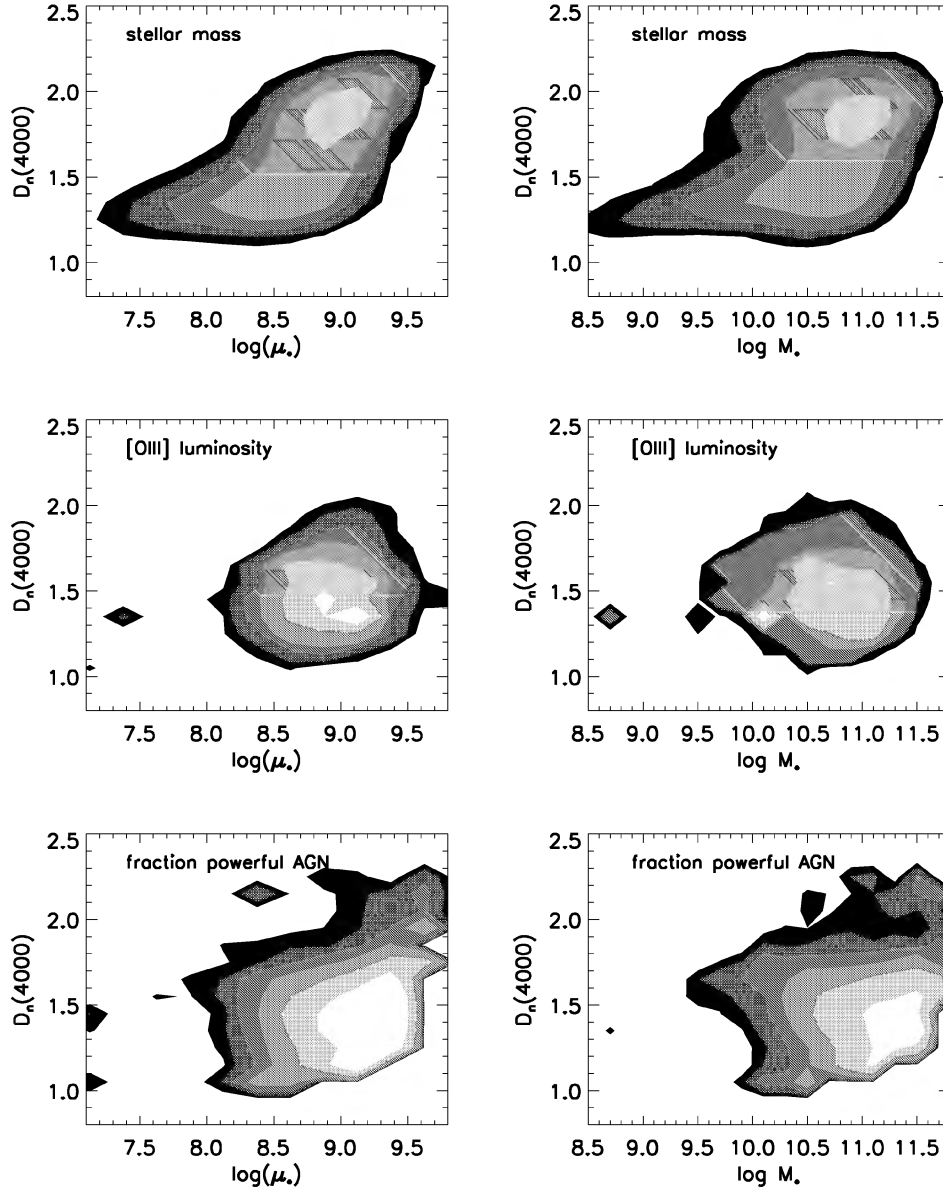

Figure 24. Top: The distribution of the total stellar mass density in the $D_n(4000)/\mu_*$ and $D_n(4000)/M_*$ planes. Middle: The distribution of the total [O III] luminosity density in AGN in the same planes. Contours indicate a factor of 2 decrease in density. Bottom: The fraction of galaxies that host powerful ($L[\text{O III}] > 10^7 L_\odot$) AGN. The contours represent AGN fractions of 0.3, 0.15, 0.07, 0.035, 0.017 and 0.008.

We therefore conclude that there is no significant difference in stellar content between the host galaxies of type 2 AGNs and QSOs with the same [O III] luminosity and redshift. This is consistent with the predictions of the unified model for AGN, and establishes that a young stellar population is associated with all types of AGN with strong [O III] emission.

In Fig. 23, we show the correlation between the [O III] line luminosities of QSOs in our sample and their continuum luminosities measured at 5007 Å. The sample is restricted to the redshifts for which it is still possible to measure the [O III] line in the SDSS spectra ($z < 0.8$). As can be seen, there is a strong correlation between the continuum and line luminosities, indicating that [O III] line luminosity is a good measure of AGN power in these systems. We note, however, that there is scatter in the relation and that selecting QSOs by line luminosity may bias the sample towards gas-rich host

galaxies, which may have higher rates of star formation. We have compared the distribution of [O III] equivalent width of our QSOs to that of the sample as a whole, and we find that there is a slight (8–10 Å) offset towards higher equivalent widths. We note that Nolan et al. (2001) found a blue component in the spectra of low-redshift QSOs, which they attributed either to star formation or to AGN light. In the Nolan et al. sample, the blue component was relatively weak, and the authors estimated that at most a few per cent of the baryonic mass of the galaxy could be involved in star formation at the epoch of observation.

6 DISCUSSION

Our main results on the properties of AGN host galaxies can be summarized as follows:

Figure 25. A montage of 48×48 arcsec² images of AGN with $[\text{O III}]$ luminosities greater than $10^{7.8} L_{\odot}$. The purple bar next to each image is 10 kpc long at the redshift of the AGN.

(i) *Stellar masses.* Type 2 AGN reside almost exclusively in massive galaxies. The fraction of galaxies with AGN declines very strongly at stellar masses below $10^{10} M_{\odot}$.

(ii) *Structural properties.* Type 2 AGN occupy host galaxies with very similar sizes and stellar surface mass densities to normal ‘early-type’ galaxies in our sample. The structural properties of AGN hosts depend very little on AGN power.

(iii) *Mean stellar ages.* The age distribution of type 2 AGN hosts is a strong function of $[\text{O III}]$ luminosity. Low-luminosity AGN have old stellar populations similar to those of early-type galaxies. High-luminosity AGN reside in significantly younger hosts and have $D_n(4000)$ distributions similar to those of normal late-type ($C < 2.6$) galaxies.

(iv) *Starbursts.* Although powerful type 2 AGN have stellar ages similar to massive late-type galaxies, a larger fraction appear to

have experienced significant bursts of star formation in the past 1–2 Gyr.

(v) *Star formation outside the nucleus.* The star formation in powerful AGN is not concentrated primarily in the nuclear regions of the galaxy, but is distributed over scales of at least several kiloparsecs.

(vi) *On-going star formation.* We interpret the parameter D (defined as the distance from the locus of star-forming galaxies in the BPT diagram) as a qualitative measure of the relative amount of on-going star formation in the galaxy. We find that type 2 AGN with small values of D have lower stellar surface mass densities and concentrations. As expected, they also have more dust and younger mean stellar ages.

(vii) *Ionization state.* We use a position angle Φ to characterize the ionization state of the AGN in our sample. We find that Φ is strongly correlated with AGN luminosity. Low-luminosity

Figure 26. A montage of 48×48 arcsec² images of AGN with [O III] luminosities greater than $10^{7.8} L_{\odot}$.

AGN have low-ionization ‘LINER-type’ emission-line ratios. High-luminosity AGN have high-ionization ‘Seyfert-type’ line ratios. There is a sharp discontinuity in the [O III] luminosity distribution at $\Phi \sim 25^\circ$, suggesting that AGN split into two distinct populations in the BPT diagram.

(viii) *Young stars in type 1 AGN.* There is no significant difference in stellar content between the host galaxies of strong type 2 AGN and QSOs with the same [O III] luminosity and redshift.

Our most striking result is that powerful AGN are found in ‘young bulges’, i.e. massive galaxies with stellar surface densities similar to early-type galaxies, but with young stellar populations. Ordinary galaxies with these characteristics are rare in the Local Universe. We illustrate this graphically in Fig. 24. The top panels show how the total stellar mass density in galaxies is partitioned among galaxies as a function of M_* , μ_* and $D_n(4000)$. The middle panels show how the total [O III] luminosity density contributed by AGN is distributed. As can be seen, most of the [O III] luminosity density comes from galaxies with M_* in the range 3×10^{10} – $10^{11} M_{\odot}$, $\mu_* \sim 10^9 M_{\odot} \text{ kpc}^{-2}$ and $D_n(4000) < 1.6$. However, there is rather little stellar mass located in this region of parameter space. At the current epoch, most of the stars located in massive, high surface density galaxies are old. The bottom panels show how the fraction of galaxies that host AGN with $L[\text{O III}] > 10^7 L_{\odot}$ varies as a function of M_* , μ_* and $D_n(4000)$. In Fig. 5 we showed that F_{AGN} defined in this way did not depend on redshift (and hence aperture). For galaxies with $M_* \sim 10^{11} M_{\odot}$, we have $F_{\text{AGN}} \sim 0.1$. Fig. 24 shows that for galaxies in this mass range with a young stellar population,

i.e. $D_n(4000) < 1.5$, the AGN fraction reaches values in excess of a third.

One interesting question is how our results fit in with other studies of active galaxies. It has often been speculated that nuclear activity and strong starbursts are both triggered by mergers or interactions between galaxies. Genzel et al. (2001) and Tacconi et al. (2002) have recently carried out a near-infrared spectroscopic study of a sample of ultraluminous infrared galaxies (ULIRGs). They find that the ULIRG velocity dispersion distribution and their location on the fundamental plane closely resemble those of intermediate-mass elliptical galaxies. The star formation rates in ULIRGs are typically around a hundred solar masses per year. A significant fraction of these objects host active nuclei and many are observed to be part of interacting or merging systems (e.g. Bushouse et al. 2002).

Canalizo & Stockton (2001) have recently studied a sample of optically selected QSOs that have far-infrared colours similar to those of ULIRGs. They propose that these objects are *transition systems*. The scenario they explore is one proposed by Sanders et al. (1988), where ULIRGs and QSOs represent different phases of a single type of event. In the Sanders et al. picture, the merging of two galaxies causes gas to flow towards the nuclear regions, triggering both starburst activity and the accretion of gas on to the black hole. Initially, the nuclear region of the merger remnant is shrouded in dust and the AGN is hidden from view. Later, as the galaxy sheds its dust cocoon, ionizing photons are able to escape, and extended [O III] emission regions appear. The end-product of the merging event is a massive early-type system.

Most imaging studies of nearby type 2 AGN have shown that, unlike the ULIRGs, only a minority of these objects exhibit obvious signs of an on-going interaction or merger (e.g. De Robertis, Hayhoe & Yee 1998, and references therein). Instead, they are typically early-type galaxies with relatively normal morphologies. It is important to note that the space density of the AGN in our sample is a factor of 100–1000 times greater than that of ULIRGs or of bright QSOs and it is therefore likely that only a restricted subset of these objects are analogues of bright QSOs or ULIRGs. A major merger is not the only process that could bring fuel to a central black hole. Minor mergers and bar-induced inflows are frequently cited mechanisms that might funnel some gas to the nucleus, thereby temporarily activating an otherwise normal galaxy, and at the same time triggering star formation that could contribute to building the bulge.

The connection between star formation and the AGN is clearest for the most powerful AGN in our sample ($L[\text{O III}] \geq 10^7 L_\odot$). We have found that the hosts of these strong AGN are either galaxies with considerable on-going star formation or post-starburst systems with ages of $\sim 10^8$ – 10^9 yr. We have extracted SDSS images of ~ 100 nearby ($z < 0.1$) AGN with $L[\text{O III}] > 10^{7.8} L_\odot$ and we find that the host galaxies fall into three broad categories:

- (i) *Single blue spheroidal/amorphous galaxies.* These are symmetric, with no close companions and no significant structure. They look like normal elliptical/S0 galaxies except that they have anomalously blue colours. In total they make up around 40 per cent of the sample.
- (ii) *Single disc galaxies.* These differ from the above in that structure outside the bright core is visible (e.g. arms, bars, dust lanes). No close companions are visible. These systems make up ~ 30 per cent of the sample.
- (iii) *Disturbed/interacting galaxies.* These have one or more close companions, and/or show obvious tidal debris. They make up ~ 30 per cent of the sample.

In Figs 25 and 26 we present a montage of the basic types of system found in our sample of powerful AGN. The images in Figs 25 and 26 suggest that many different physical processes may be responsible for fuelling black holes and building bulges. If this is the case, it becomes even more of a challenge to understand why there is such a tight connection between black hole mass and bulge mass.

The presence in our sample of a substantial number of spheroidal galaxies with apparently normal structure but young stellar populations suggests that powerful type 2 AGN, like QSOs, may be a late stage of a merger/starburst. In Section 4.5 we found that many powerful type 2 AGN have radial gradients in their stellar populations, with the stars near the nucleus exhibiting larger 4000-Å break strengths than the stars a few kiloparsecs away. This can be explained if the *mass fraction* of stars formed in the burst increases as a function of radius. It would then take substantially longer for the 4000-Å break to revert back to values characteristic of normal ellipticals in the main bodies of galaxies than in their nuclei. Begelman (1985) has proposed that X-rays from the active galactic nucleus can produce runaway heating of the interstellar medium and result in central ‘holes’ in the distribution of cold gas in active galaxies. The AGN itself could thus regulate the amount of star formation that occurs at the centres of galaxies.

Quite apart from any specific scenario, our principal result has an appealingly simple interpretation. The two necessary ingredients for a powerful AGN are a massive black hole and an abundant fuel supply. Only massive early-type galaxies contain

massive black holes, and only galaxies with significant amounts of recent/on-going star formation have the requisite fuel supply. This combination is rare today, but evidently was not so at high redshift.

Further clues to the connection between type 2 AGN, QSOs, ULIRGs and radio galaxies will come from direct cross-correlation of our sample with infrared and radio surveys such as *IRAS* and *FIRST* (e.g. Ivezić et al. 2002). In addition, the SDSS offers unprecedented opportunities for a detailed comparison of the environments of AGN with those of normal galaxies. Our analysis has demonstrated a clear link between type 2 AGN and the formation or evolution of massive early-type galaxies. The challenge is now to understand this connection in more detail.
